ABSTRACT

The setup adjustment problem occurs when a machine experiences an upset at setup that needs to be compensated for. In this article, feedback methods for the setup adjustment problem are studied from a small-sample point of view, relevant in modern manufacturing. Sequential adjustment rules due to Grubbs (Grubbs, F. E. (1954). An optimum procedure for setting machines or adjusting processes. Industrial Quality Control July) and an integral controller are
considered. The performance criteria is the quadratic off-target cost incurred over a small number of parts produced. Analytical formulae are presented and numerically illustrated. Two cases are considered, the first one where the setup error is a constant but unknown offset and the second one where the setup error is a random variable with unknown first two moments. These cases are studied under the assumption that no further shifts occur after setup. It is shown how Grubbs’ harmonic rule and a simple integral controller provide a robust adjustment strategy in a variety of circumstances. As a by-product, the formulae presented in this article allow to compute the expected off-target quadratic cost when a sudden shift occurs during production (not necessarily at setup) and the adjustment scheme compensates immediately after its occurrence.

Key Words: Process adjustment; Stochastic approximation; Integral control.

1. INTRODUCTION

Suppose that due to a defective setup machine operation, the quality characteristic generated by a production process is in a state of statistical control but the process starts off-target. Adjusting the process is justified if the only relevant cost is the cost of running the process off-target. Sequential adjustment rules for this problem were proposed by Grubbs (1983) (originally published in Grubbs (1954)). These rules have been shown to derive from a much broader class of setup adjustment problems based on stochastic control methods by del Castillo et al. (2002). In this article, the small sample performance of Grubbs’ adjustment rules are studied and contrasted with other feedback adjustment methods.

To introduce some basic notation that will be used in what follows, let $Y_t$ denote the observed deviation from target of some quality characteristic of interest. Following Grubbs (1954), a simple but useful model for the setup adjustment problem is to assume

$$Y_t = d + U_{t-1} + v_t = \mu_t + v_t$$ (1)

where $d$ is the setup error, $U_t$ is the level of the controllable factor set after producing part $t$ (this will have an immediate effect on part $t+1$), $\mu_t$ is the mean deviation from target for part $t$, and $v_t \sim N(0, \sigma_v^2)$ models both the part-to-part variability and the measurement error.
Two different control rules were derived by Grubbs depending on two sets of assumptions made on the setup error $d$:

1. If $d$ is an unknown constant, minimization of $\text{Var}(\mu_{n+1})$ subject to $E[\mu_{n+1}] = 0$ results in Grubbs’ “harmonic rule”:

$$U_t = -\tilde{d}_t, \quad \tilde{d}_t = \tilde{d}_{t-1} + K_t Y_t, \quad K_t = 1/t$$

(2)

or

$$U_t - U_{t-1} = \nabla U_t = -\frac{Y_t}{t}$$

thus the weights $K_t$ follow a harmonic series. An initial (a priori) estimate $\tilde{d}_0$ is required to set the first setting of the controllable factor at $U_0 = -\tilde{d}_0$. del Castillo et al. (2002) point out how adjustment rule (2) is a particular case of Robbins and Monro’s (1951) celebrated stochastic approximation method. Therefore, this article contains (indirectly) a small-sample performance study of stochastic approximation methods applied to the simple case of estimation of an unknown constant.

2. If $d \sim N(\bar{d}, \sigma_d^2)$ with both $\bar{d}$ and $\sigma_d^2$ known, minimization of $E[\sum_{i=1}^{n} \mu_i^2]$ is achieved by Grubbs’ second adjustment rule. In this case,

$$\tilde{d}_t = \tilde{d}_{t-1} + K_t Y_t, \quad K_t = \frac{1}{t + (\sigma_\tau^2/\sigma_d^2)}$$

and

$$\nabla U_t = -K_t Y_t.$$  \hspace{1cm} (3)

This rule is called Grubbs’ “extended” rule by Trietsch (1998).

del Castillo et al. (2002) provide a Bayesian formulation based on a Kalman filter to the solution of the second setup adjustment problem above (random $d$) that yields Grubbs extended rule as a solution. Define the posterior variance of $\mu_t$ as $P_t = \text{Var}(\mu_t | Y_t, Y_{t-1}, \ldots, Y_1)$. The Kalman filter formulation yields in this case (see del Castillo et al. (2002)):

$$P_t = \frac{P_{t-1} \sigma_\tau^2}{\sigma_\tau^2 + P_{t-1}} = \frac{\sigma_\tau^2 P_0^2}{\sigma_\tau^2 + t P_0}$$

$$\tilde{d}_t = \tilde{d}_{t-1} + K_t Y_t,$$

$$K_t = \frac{1}{t + (\sigma_\tau^2/P_0)}, \quad \text{and} \quad \nabla U_t = -K_t Y_t.$$ \hspace{1cm} (4)

The interpretation is that, a priori, $d \sim (\tilde{d}_0, P_0)$. Thus for Grubbs’ extended rule to be optimal with respect to $E[\sum_{i=1}^{n} \mu_i^2]$ we need to know $\bar{d}$ (so we can set $\tilde{d}_0 = \bar{d}$) and $\sigma_d^2$ and $\sigma_\tau^2$ must be known for us to use Eq. (3). Evidently, if $P_0 = \sigma_d^2$, Eqs. (3) and (4) are identical. Note how under this
interpretation, if there is no prior information on the offset ($P_0 \to \infty$) Eq. (4) is equivalent to Eq. (2), Grubbs’ simpler harmonic rule.

A pure Bayesian point of view will stop after stating the solution (4). It is still of practical interest, however, to study how this rule behaves if the prior distribution is not exactly equal to the true setup distribution. In other words, what if $\bar{d}$ and $\sigma_d^2$ are not known but someone still applies Grubbs’ extended rule with $P_0 \neq \sigma_d^2$ and/or $d_0 \neq \bar{d}$? The opposite is also of interest: to study the performance of Grubbs’ simpler harmonic rule under the assumption of a random setup error.

An additional adjustment rule that will be contrasted is an integral controller (Box and Luceno, 1997):

$$\nabla U_t = -\lambda Y_t$$  \hspace{1cm} (5)

which, contrary to Grubb’s rules, does not converge to zero since $\lambda$ is a constant.

The remainder of this article is organized as follows. Section 2 presents the small sample performance indices which will be used to compare the three adjustment rules given by Eqs. (2), (4), and (5). Given the emphasis in modern manufacturing for short production runs, the performance analysis in this article focuses on the performance for a small number of parts. Section 3 shows the numerical results for the case the setup error is an unknown constant. Section 4 presents the corresponding results for the random setup error case. All the numerical results in Secs. 3 and 4 were obtained analytically and are not based on simulation. The article concludes with a summary of results.

2. PERFORMANCE INDICES FOR SMALL SAMPLES

The performance indices that will be used in the remainder of this article are presented in this section for the two cases considered by Grubbs.

Consider first the case where the setup error $d$ is an unknown constant or “offset.” For this case, the performance index considered is the scaled Average Integrated Square Deviation (AISD) incurred over $m$ time instants or parts. This is defined for integer $m > 0$ as:

$$\text{AISD}(m) = \frac{1}{m\sigma_Y^2} \sum_{i=1}^{m} E[Y_i^2] = \frac{1}{m\sigma_Y^2} \sum_{i=1}^{m} (V[Y_i] + E[Y_i] + E[Y_i]^2).$$  \hspace{1cm} (6)

The AISD is a common performance index in the control engineering literature. Since $Y_i$ models deviations from target, the AISD index is like
an average “variance plus squared bias” calculation, and is a surrogate of a quadratic off-target “loss” function. We avoid dependency on $\sigma_v^2$ by dividing by this quantity.

One important byproduct of the AISD formulae (presented later in the article) is that they provide a measure of the quadratic cost incurred by a process after a shift of size $d$ occurs \textit{at any point in time} (not only at startup) assuming the process is adjusted after the occurrence of the shift with one of the adjustment policies here discussed.

Consider now the case where the setup error $d$ is a random variable. The performance measure to be used when $d$ is random is once again the AISD but we need to account for the additional variability in the setup error, so we define

$$\text{AISD}_d(m) = \frac{1}{m\sigma_v^2} E_d \left[ \sum_{i=1}^{m} E[Y_{it}^2] \right] = \frac{1}{m\sigma_v^2} \int_{-\infty}^{\infty} \sum_{i=1}^{m} E[Y_{it}^2] f_d(x) \, dx$$

where the outer expectation is taken over the distribution of $d$. Note that if $d$ is a non-random constant, then $\text{AISD}(m) = \text{AISD}_d(m)$. The case when $d$ is normal with known mean and known variance was discussed by Trietsch (1998). Under such conditions, Grubbs’ extended rule is optimal for the $\text{AISD}_d$ criterion.

### 3. PERFORMANCE FOR AN UNKNOWN CONSTANT SETUP ERROR

Suppose $d$ is an unknown constant but unaware of this fact a user applies Grubbs’ extended rule (i.e., the Kalman filter adjustment scheme given by Eq. (4)) to the process. It is shown in Appendix A that this rule applied to the process $Y_i = d + U_{i-1} + v_i$ (with $d$ constant) results in

$$\frac{E[Y_i]}{\sigma_v} = \frac{A}{B_1(t - 1) + 1}$$

and

$$\frac{V[Y_i]}{\sigma_v^2} = 1 + \frac{t - 1}{(1/B_1 + t - 1)^2}$$

where $A = (d - \hat{d}_0)/\sigma_v$ measures how far off the initial estimate of the offset was. The quantity $B_1 = P_0/\sigma_v^2$ is a measure of the “confidence” on the initial offset estimate.
To study the performance of Grubbs’ adjustment rules, Eqs. (8) and (9) can be substituted into Eq. (6) and the sum computed for given values of $A$, $B_1$, and $m$. Note that our analytic expressions are exact and avoid use of simulation to estimate the $\text{AISD}(m)$. Alternatively, an expression for the sum in $\text{AISD}(m)$ is given by formula (17) in Appendix A which can be easier to use if a software that computes the polygamma function is available (e.g., Mathematica or Maple). We note that the corresponding expressions for Grubbs’ harmonic rule are obtained from Eqs. (8) and (9) by letting $B_1 \to \infty$.

For a discrete integral controller (or EWMA controller), it can be shown that

$$
\frac{E[Y_i]}{\sigma_i} = (1 - \lambda)^{t-1} A
$$

and

$$
\frac{V[Y_i]}{\sigma_i^2} = \frac{2 - \lambda(1 - \lambda)^{2(t-1)}}{2 - \lambda}
$$

from where $\text{AISD}(m) = (1/m\sigma_i^2) \sum_{i=1}^{m}(E[Y_i]^2 + V[Y_i])$ can be computed or one can use the closed-form expression (Eq. (18)) in Appendix A. The $\text{AISD}(m)$ expressions allow to study the trade-offs between the sum of the variances and the sum of squared expected deviations (squared bias). For the Kalman filter scheme, as $B_1 = P_0/\sigma_i^2 \to 0$, implying increasingly higher confidence in the a priori offset estimate, then $m^{-1} \sum_{i=1}^{m} V[Y_i]/\sigma_i^2 \to 1$ (i.e., we get lower variance), but $m^{-1} \sum_{i=1}^{m} E[Y_i]^2/\sigma_i^2 \to A^2$ (i.e., we get larger bias). Similarly, for the EWMA or integral controller, as $\lambda \to 0$, implying less weight given to the last observation we have that $m^{-1} \sum_{i=1}^{m} V[Y_i]/\sigma_i^2 \to 1$ (lower variance), but $m^{-1} \sum_{i=1}^{m} E[Y_i]^2/\sigma_i^2 \to A^2$ (larger bias).

The performance of the following adjustment rules was evaluated based on the AISD criterion (in all cases, adjustments are given by $\nabla U_t = -\nabla d_t$):

1. Grubbs harmonic rule, where $\hat{d}_t = \hat{d}_{t-1} + Y_t/t$.
2. Kalman filter rule 1 (assumes $\sigma_i^2$ is known), where $\hat{d}_t = \hat{d}_{t-1} + (Y_t/(\sigma_i^2/P_0 + t))$. This is equivalent to Grubbs’ extended rule.
3. Kalman filter rule 2 which is same as above but $\sigma_i^2$ is estimated on-line from $z_t = Y_t - U_{t-1}$ using only the data available at time $t$. 
4. Discrete integral controller (EWMA controller), where \( \hat{d}_t = \hat{d}_{t-1} + \lambda Y_t \).

There are two parameters that can be modified in Grubbs’ adjustment rules: \( \hat{d}_0 \) and \( P_0 \). The effect of these parameters can be studied from looking at the effect of changes in \( A \) and \( B_1 \), as previously defined. Therefore, the four scenarios presented in Table 1 were investigated. In Table 1, if the initial prior variance \( P_0 \) is large relative to \( \sigma^2 \) (i.e., if \( B_1 \) is large), the weights \( K_t \) will be close to \( 1/t \) (Grubbs’ harmonic rule), i.e., the initial estimate \( \hat{d}_0 \) will be discounted faster. This turns out to be a “good” choice if the initial offset estimate is far from \( d \), where the distance between \( d \) and \( \hat{d}_0 \) is measured relative to \( \sigma \), by the quantity \( A \). A similar good decision is when \( P_0 \) is low and \( \hat{d}_0 \) is a good estimate of the offset (\( B_1 \) small, \( |A| \) small). In such case, \( K_t < 1/t \), so there will be a slower discounting of the initial estimate \( \hat{d}_0 \). Cases 2 and 3 on the table indicate “bad” choices, when the selected value of \( P_0 \) does not reflect how good the initial offset estimate really is. Since in the absence of historical information it is difficult to know a priori the value of \( d \) it is of practical interest to study the four cases on the table.

Table 2 contrasts the AISD performance of Grubbs’ harmonic rule, the discrete integral controller (EWMA controller) and the Kalman filter adjusting scheme (\( \sigma^2 \) known). The table shows the values of \( \sqrt{\text{AISD}(m)} \) for \( m = 5, 10, \) and \( 20 \). As can be seen from the table, the “gap” between the column minimum and the \( \sqrt{\text{AISD}} \) provided by Grubbs rule shrinks as the offset \( d \) gets much larger than \( \sigma \) (i.e., as the error \( |A| \) increases). This gap, however, is quite moderate except in the case where one is very confident (\( B_1 = P_0/\sigma^2 \) small) of our a priori offset estimate and the a priori offset estimate turns out to be quite accurate (i.e., \( A = 0 \)). This is not a practical case because it implies we practically know the value of the offset \( d \).

If \( A = 0 \), it can be seen from Eqs. (8) and (10) that the AISD indices equal the average scaled variance since the deviations from target will

always equal zero on average. If \( d = \hat{d}_0 = 0 \), the \( \sqrt{\text{AISD}} \) quantifies the average inflation in standard deviation we will observe for adjusting a process when there was no need to do so. Note that for \( A = 0 \) (no offset), one can get an inflation in standard deviation equal to zero if \( B_1 = 0 \) in the Kalman filter scheme or if \( \lambda = 0 \) in the integral control scheme. This inflation in standard deviation has been studied, for discrete

Table 2. Kalman filter adjusting scheme (\( \sigma^2 \) known), Grubbs' harmonic rule and integral controller \( \sqrt{\text{AISD}} \) performance. \( A = (d - \hat{d}_0)/\sigma_v \). \( B_1 = P_0/\sigma_v^2 \).

Bold numbers are minimums by column.
integral controllers, by Box and Luceno (1997) and del Castillo (2001), although these authors looked at asymptotic standard deviations, and not at small-sample standard deviation as we do here.

Perhaps it should be pointed out that if one were extremely confident on the estimate of the offset of the machine \( B_1 \to 0 \), simply setting \( U_t = -d_0 \) for \( t = 0, 1, \ldots \) will result in an on-target process assuming we indeed have \( d_0 = d \). Thus, for most practical cases where a sequential adjustment rule is needed, the Kalman filter rule (and Grubbs’ extended rule) does not perform significantly better than Grubbs’ harmonic scheme in the case of a constant unknown setup error.

Intuitively, if the variance \( \sigma^2 \) is unknown the performance of the Kalman filter scheme (Grubbs’ extended rule) can only worsen. This was confirmed by estimating AISD using simulation. Thus Grubbs harmonic rule is also superior, in the single realization case, to the Kalman filter scheme with variance unknown.

Turning to the discrete integral controller, it can be seen that it also provides a very competitive scheme compared to the Kalman filter (Grubbs’ extended rule) scheme. The parameter \( \lambda \) has the effect of bringing the process back to target more rapidly the larger \( \lambda \) is. The trade-off is that there is an increase, for small \( A \), of the \( \sqrt{\text{AISD}} \) index as \( \lambda \) is increased. That is, the inflation in standard deviation due to unnecessarily adjusting an on-target process \( (d = 0, A = 0) \) increases as \( \lambda \) increases. From the table, it appears the value \( \lambda = 0.2 \) provides a relatively good trade-off between fast return to target and inflation of standard deviation if the process is really on-target (no offset).

**Adjusting Only the First Few Times**

It could be argued that in practice, only the first few adjustments will be implemented after which no further adjustments are made to the machine. The machine then runs at the final setting that resulted at the end of the adjustments until completion of the batch of \( N \) parts. The performance of the adjustment rules should be investigated on this assumption instead. For this reason, let \( m \) denote the number of adjustments implemented in a batch of size \( N \) parts produced. For discrete \( m \) such that \( 1 \leq m \leq N \), the average integrated squared deviation index is defined as:

\[
\text{AISD}(m, N) = \frac{m \text{AISD}(m)}{N} + \frac{(N - m)(V[Y_{m+1}] + E[Y_{m+1}]^2)}{N \sigma^2}.
\]

Performance of Setup Adjustment Methods 931
Closed-form expressions for $\text{AISD}(m, N)$ for the Kalman filter, Grubbs' harmonic, and discrete integral control rules can be found in Appendix A. They were used to produce Table 3 where the $\sqrt{\text{AISD}(m, N)}$ performance indices were computed. Clearly, if $m = N$, then $\sqrt{\text{AISD}(m, N)} = \sqrt{\text{AISD}(m)}$.

From Table 3 and similar computations for other values of $m$ and $N$, it was observed that the conclusions expressed before based on the $\text{AISD}(m)$ index, which measures off-target cost only while the adjustments take place, are practically unchanged if we consider in addition the cost incurred after adjustments stop and the process keeps operating. Only when $A \to 0$ (no offset or perfect offset estimate) and $B_1 = P_0^2 / \sigma^2_d$ is small, the Kalman filter rule outperforms the harmonic rule. The discrete integral controller with $\lambda = 0.2$ is a good intermediate value that balances a rapid return to target for large offsets with a low inflation in variance in case the process was really on-target but we nevertheless adjust.

### 4. PERFORMANCE WHEN THE SETUP ERROR IS A RANDOM VARIABLE

Suppose now that the offset $d$ is a random variable such that $d \sim (d_0, \sigma^2_d)$. Note that no assumption on the distribution of $d$ is made. We wish to evaluate the performance of the different adjustment methods by averaging over the possible realizations of the random offset $d$.

**Table 3.** Kalman filter adjusting scheme ($\sigma^2_d$ known), Grubbs' harmonic rule and I-controller $\sqrt{\text{AISD}(10, 100)}$ performance. Ten adjustments were made after which 90 additional parts were produced. $A = (d - \hat{d}_0)/\sigma_d, B_1 = P_0^2/\sigma^2_d$. Bold numbers are minimums by column.

**Bold numbers are minimums by column.**
As mentioned earlier, if the mean and variance of \( d \) are known, then the Kalman filter scheme, and hence, Grubbs extended rule are optimal for a quadratic loss function such as our AISD\(_d\) criterion. This was the case discussed by Grubbs (1983) and Trietsch (1998). In this section we consider the more general case when the mean and variance of \( d \) are both unknown.

When \( d \) is random, we need to use a prior estimate \( \hat{d}_0 \) with associated variance \( P_0 \) to start the Kalman filter scheme (4). The situation is depicted in Fig. 1.

Using Eq. (7) as our performance index, it is shown in Appendix B that for the Kalman Filter (KF) scheme:

\[
\text{AISD}_d(m)_{\text{KF}} = C_1(B_2 + A_2^2) + C_2
\]

Figure 1. Starting the Kalman filter scheme, \( \hat{d}_0 \) and/or \( \sigma_d^2 \) unknown.
where \( A_2 = (\tilde{d}_0 - \hat{d}_0)/\sigma_v \) is a measure of the average error in the offset estimate, \( B_2 = \sigma_v^2/\sigma_v^2 \) is a measure of the variability of the setup, and \( C_1 \) and \( C_2 \) (and \( C_3 \) used next) are functions of \( B_1 = P_0/\sigma_v^2 \) and \( m \) shown in Appendix A. For Grubbs’ (G) harmonic rule this reduces to:

\[
AISD_d(m)_G = \frac{B_2 + A_2^2}{m} + C_3. \tag{13}
\]

Recall that \( B_1 \) is a measure of confidence in \( \hat{d}_0 \), therefore, since \( \sigma_v^2 \) is not known, we have that in general \( B_1 \neq B_2 \). Closed-form expressions can be obtained for \( AISD_d(m)_{\text{EWMA}} \), see Appendix B.

The \( AISD_d \) performance of the Kalman filter approach, Grubbs basic harmonic rule, and that of an integral controller were evaluated using Eqs. (12), (13), and (22). Figure 2 shows cases when the Kalman filter approach is better than Grubbs’ harmonic rule for different values of \( B_1, B_2, A_2, \) and \( m \).

The shaded regions correspond to cases where \( AISD_d(m)_{\text{KF}} < AISD_d(m)_G \). As it can be seen, for large average offsets (\( A_2 \) large) and/or large setup noise (\( B_2 \) large), Grubbs harmonic rule is better. Here “large” and “small” are terms relative to the process variance \( \sigma_v^2 \). The advantage of the harmonic rule over the Kalman filter scheme decreases with increasing value of \( B_1 = P_0/\sigma_v^2 \). Note that under the assumptions in Case 1 above (when \( \tilde{d}_0 \) and \( \sigma_v^2 \) are known), i.e., when we have that \( B_1 = B_2 \) and \( A_2 = 0 \), the Kalman filter method always dominates Grubbs harmonic rule. This agrees with our earlier comment which

![Figure 2. Kalman filter and Grubbs harmonic rule performance, random setup error. Shaded regions indicate cases when AISD_d(m)_KF < AISD_d(m)_G.](image-url)
indicated that the Kalman filter scheme (and Grubbs extended rule) is optimal for the AISD criterion if the parameters are known.

Figures 3 and 4 compare the AISD performance of the Kalman filter approach with that of an Integral controller with $\lambda = 0.2$ and $\lambda = 0.1$, respectively.

Figure 3. Kalman filter and discrete integral (EWMA) controller (with $\lambda = 0.2$) performance, random setup error. Shaded regions indicate cases for which $AISD_d(m)_{KF} < AISD_d(m)_{EWMA}$. $B_1 = P_0/\sigma^2$, $B_2 = \sigma_d^2/\sigma^2$, $A_2 = |d_0 - \hat{d}_0|/\sigma$.

Figure 4. Kalman filter and discrete integral (EWMA) controller (with $\lambda = 0.1$) performance, random setup error. Shaded regions indicate cases for which $AISD_d(m)_{KF} < AISD_d(m)_{EWMA}$. $B_1 = P_0/\sigma^2$, $B_2 = \sigma_d^2/\sigma^2$, $A_2 = |d_0 - \hat{d}_0|/\sigma$. 
As it can be seen, the Kalman filter scheme is to be preferred over more cases as the number of observations $m$ increases. The integral controller should be preferred when the average offset is large ($A_2$ large) and/or the setup is very variable (large $B_2$). This is even more true as the confidence in the initial offset mean decreases (i.e., the larger $B_1$). Observe how for cases where the average offset is very small the integral controller also dominates the Kalman filter approach.

Finally, Fig. 5 shows the AISD comparison between Grubbs’ harmonic rule and an integral controller. The integral controller outperforms the harmonic rule for cases near the origin, when $A_2$ is small (small average error in offset estimate) and $B_2$ is small (low setup variance). As the sample size increases, Grubbs’ harmonic rule dominates the integral controller scheme.

5. CONCLUSIONS AND FURTHER RESEARCH

The small sample properties of Grubbs (1983) adjustment schemes and that of an integral controller were analyzed for the case a setup error is systematic (nonrandom) and when it is a random variable with unknown mean and variance. The performance metric used was a quadratic off-target cost. It was assumed that a shift or “offset” can only occur at setup.
If the setup error is an unknown constant it was shown that for most practical cases when sequential adjustment is necessary, Grubbs (1983) harmonic rule represents a better strategy than the Kalman filter scheme (and therefore it performs better than Grubbs’ extended rule).

The even simpler integral or EWMA controller with weight $\lambda = 0.2$ provides a competitive alternative to the harmonic rule for cases when the offset is small (in the order of less than one standard deviation of the process). It was shown that these conclusions remain essentially unchanged if the performance is evaluated based not only while adjustments take place but also by considering additional runs in which no further adjustments are made to the process.

If the setup error is instead a random variable, an integral controller performs better than the Kalman filter scheme when the setup noise is relatively high and the offset is very large on average. When the offset is large and/or the setup noise is large, Grubbs harmonic rule outperforms the Kalman filter scheme. The analytic formulae in Appendix B allow to obtain similar results for other values of the process and controller parameters without recourse to simulation. Further recommendations about when to use each method in the random setup error case can be reached by looking at Figs. 2–5.

The main advantage of the discrete integral controller over the other methods considered in this article is that it stays alert for compensating for further shifts in the process that occur while in manufacturing (i.e., not at setup). The weights in Grubbs rule, for example, would have to be reset every time a shift is detected. This points toward integration of the adjustment schemes with a detection mechanism that will trigger the adaptation of the weights, along the lines recently followed by Guo et al. (2000). Such integrated SPC/EPC approaches require further research (for recent work on this topic, see Pan, 2002). The important connection between Grubbs harmonic rule and Robbins and Monro’s Stochastic Approximation method (Robbins and Monro, 1951) point out to a very large body of literature and theoretical results some of which may prove useful in process adjustment applications.

### APPENDIX A: MEAN AND VARIANCE OF THE QUALITY CHARACTERISTIC AND AID FORMULAE FOR AN UNKNOWN CONSTANT SETUP ERROR

The set point at time $t$ is given by $U_t = -\sum_{i=1}^t K_i Y_i - \hat{\alpha}_0$. Thus, $Y_t = d - \hat{d}_0 - \sum_{i=1}^{t-1} K_i Y_i + \nu_t$. So, for $t = 1$ we have that

$$Y_1 = d - \hat{d}_0 + \nu_1$$  \hspace{1cm} (14)
from which $\frac{E[Y_1]}{\sigma_y} = (d - \hat{d}_0)/\sigma_y = A$ and $V[Y_1]/\sigma_y^2 = 1$ (compare with Eqs. (8) and (9)). Given that the weights are equal to

$$K_i = \frac{1}{\sigma_i^2/P_0 + t},$$

we have that

$$Y_t = \frac{(d - \hat{d}_0)(\sigma_y^2/P_0)}{(\sigma_i^2/P_0) + 1} \prod_{i=2}^{t-1} \left(1 - \frac{1}{(\sigma_i^2/P_0) + i}\right) + f_1 v_1 + f_2 v_2 \ldots + f_{t-1} v_{t-1} + v_t$$

(15)

where the quantities $\{f_k\}_{k=1}^{t-1}$ are functions of $\sigma_i^2/P_0$ but not of $d$ or $\hat{d}_0$. After some algebra, Eq. (15) simplifies to:

$$Y_t = \frac{(d - \hat{d}_0)(\sigma_y^2/P_0)}{(\sigma_i^2/P_0) + 1} \left( \frac{(P_0/\sigma_i^2) + 1}{(P_0/\sigma_i^2) - (P_0/\sigma_i^2) + 1} \right)$$

$$+ f_1 v_1 + f_2 v_2 \ldots + v_t.$$

Taking expected value and variance in the previous expression results in Eqs. (8) and (9).

An expression for

$$\text{AISD}(m) = \frac{1}{m\sigma^2} \sum_{i=1}^{m} (V[Y_i] + E[Y_i]^2)$$

(16)

can be obtained after some algebra from properties of the sums involved. Define

$$C_1 = \frac{\Psi(1/B_1) - \Psi(m + 1/B_1)}{B_1^2 m}$$

and

$$C_2 = \frac{B_1[\Psi(m + 1/B_1) - \Psi(1/B_1)] + \Psi(m + 1/B_1) - \Psi(1/B_1) + 1}{B_1 m}$$

where $\Psi(x) = d \ln \Gamma(x)/dx$ (Psi or digamma function), and $\Psi'(x) = d \Psi(x)/dx$ (trigamma function). If a software is available that computes these functions, finding the AISD is facilitated by the formula.

Then, Eq. (16) can be written as:

$$\text{AISD}(m) = C_1 A^2 + C_2.$$
Performance of Setup Adjustment Methods

Taking limit as $B_1 \to \infty$, we get a simple formula for the AISD given by Grubbs harmonic rule:

$$\text{AISD}_G(m) = 1 + \frac{\Psi(m) + \gamma + A^2}{m} = A^2/m + C_3$$

where $\gamma \approx 0.5772156$ is Euler’s constant and

$$C_3 = 1 + \frac{\Psi(m) + \gamma}{m}.$$

For the discrete integral (or EWMA) controller, the corresponding expression for the AISD is given directly from Eqs. (10) and (11):

$$\text{AISDEWMA}(m) = \frac{2}{2 - \lambda} + \left(\frac{1 - (1 - \lambda)^2}{m(2 - \lambda)}\right) \left(\frac{A^2}{\lambda} - \frac{1}{2 - \lambda}\right).$$

Adjusting Only the First Few Items

Closed-form expressions for $\text{AISD}(m, N)$ can be obtained by direct substitution of the $\text{AISD}(m)$ formulae presented above into:

$$\text{AISD}(m, N) = \frac{m\text{AISD}(m)}{N} + \frac{(N - m)(V[Y_{m+1}] + E[Y_{m+1}^2])}{N\sigma^2}.$$  

After some algebra, for the Kalman filter scheme this turns out to be:

$$\text{AISDKF}(m, N) = \frac{m}{N}(A^2C_1 + C_2) + \frac{N - m}{N} \left(1 + \frac{mB_1^2 + A^2}{(1 + mB_1)^2}\right).$$  

where $C_1$, and $C_2$ are the functions of $m$ and $B_1$ defined before. If $B_1 \to \infty$, one gets the corresponding expression for Grubbs harmonic rule:

$$\text{AISD}_G(m, N) = 1 + \frac{A^2 + \Psi(m) - 1}{N} + \frac{1}{m}.$$  

(20)
Finally, for the discrete integral (EWMA) controller this turns out to be

$$\text{AISD}_{\text{EWMA}}(m, N)$$

$$= \frac{1}{N} \left\{ \frac{2m}{2-\lambda} + \frac{1 -(1 - \lambda)^{2m}}{2-\lambda} \left( \frac{A^2}{\lambda} + \frac{1}{2-\lambda} \right) \right\}$$

$$+ \frac{1}{N} \left\{ (N-m) \left[ \frac{2 - \lambda (1-\lambda)^{2m}}{2-\lambda} + (1-\lambda)^{2m} A^2 \right] \right\}.$$

(21)

APPENDIX B: AISD$_d$ (RANDOM SETUP ERROR) FORMULAE

Assume that $\hat{d}_0$ and/or $\sigma_d^2$ are unknown. We have that $\text{AISD}_{\text{KF}}(m) = C_1 A^2 + C_2$. The expression for $\text{AISD}_d(m)$ is obtained from its definition as follows

$$\text{AISD}_d(m)_{\text{KF}} = \int_{-\infty}^{\infty} \text{AISD}_{\text{KF}}(m) f_d(x) \, dx$$

$$= C_1 \int_{-\infty}^{\infty} \frac{(d - \hat{d}_0)^2}{\sigma_d^2} f_d(x) \, dx + C_2 \int_{-\infty}^{\infty} f_d(x) \, dx$$

$$= \frac{C_1}{\sigma_d^2} \int_{-\infty}^{\infty} (d^2 - 2d \hat{d}_0 + \hat{d}_0^2) f_d(x) \, dx + C_2$$

Since $\int_{-\infty}^{\infty} d^2 f_d(x) \, dx = \sigma_d^2$ and $\int_{-\infty}^{\infty} d f_d(x) \, dx = \hat{d}_0$, then

$$\text{AISD}_d(m)_{\text{KF}} = \frac{C_1}{\sigma_d^2} (\sigma_d^2 + (\hat{d}_0 - \hat{d}_0)^2) + C_2$$

$$= C_1 (B_2 + A_2^2) + C_2.$$ 

The $\text{AISD}_d(m)$ formula for Grubbs’ harmonic rule is obtained in a similar way. Note that the $\text{AISD}_d$ depends only on the mean and variance of $d$. For the integral (or EWMA) controller, the corresponding expression is

$$\text{AISD}_d(m)_{\text{EWMA}} = \frac{2}{2-\lambda} + \frac{1 -(1 - \lambda)^{2m}}{(2-\lambda)m} \left[ \frac{B_2 + A_2^2}{\lambda} - \frac{1}{2-\lambda} \right].$$

(22)
Performance of Setup Adjustment Methods

It is possible to obtain $\text{AISD}_d(m, N)$ formulae for when only the first few adjustments are implemented using each method, and this can be useful to determine the optimal number of adjustments when considering the performance of the adjustment scheme under random setup errors.
